In Brief

Is the same ensemble of neurons always dedicated to the same learning? Matsuo shows that suppression of neuronal ensembles activated during initial learning hinders relearning. This ensemble inflexibility could ensure the strengthening of synaptic connections across a specific subset of neurons by repetitive activation, thereby enabling memory enhancement.

Highlights

- Inhibiting learning-activated neural ensembles impairs memory retrieval
- Inhibiting neural ensembles activated during learning impairs relearning
- Inhibiting neural ensembles for a specific memory does not hinder distinct learning

SUMMARY

Lesion studies suggest that an alternative system can compensate for damage to the primary region employed when animals acquire a memory. However, it is unclear whether functional compensation occurs at the cellular ensemble level. Here, we inhibited the activities of a specific subset of neurons activated during initial learning by utilizing a transgenic mouse that expresses tetanus toxin (TeNT) under the control of the *c-fos* promoter. Notably, suppression interfered with relearning while sparing the ability to acquire and express fear memory for a distinct context. These results suggest that the activity of the initial ensemble is preferentially dedicated to the same learning and that it is not replaceable once it is allocated. Our results provide substantial insights into the machinery underlying how the brain allocates individual memories to discrete neuronal ensembles and how it ensures that repetitive learning strengthens memory by reactivating the same neuronal ensembles.

INTRODUCTION

External information acquired through daily experiences can be internally represented and stored in the brain across several interacting regions as a memory. Recent innovative studies have begun to present direct evidence that individual memories reside in the activities of specific spatially distributed neuronal populations within neuronal networks. For instance, activity manipulation of a small, specific, dispersed subset of neurons that was activated during a learning paradigm enabled memory operations including artificial retrieval and association of a previously obtained memory in mice (Garner et al., 2012; Liu et al., 2012; Ramirez et al., 2013). These studies provided a causal sufficiency between memory engrams and the activities of specific ensembles of neurons.

The next critical question arising from this idea is how specific subsets of neurons are chosen from a large population of neurons to encode a given memory (Silva et al., 2009). Findings from recent research suggested a potential mechanism that involves

neuronal competition. A subset of lateral amygdala neurons, in which cyclic AMP responsive element binding protein (CREB) was virally overexpressed, preferentially participated in auditory fear memory formation (Han et al., 2007). Moreover, the higher levels of CREB expression have been suggested to increase the intrinsic excitability of the neuron (Zhou et al., 2009). Thus, it is likely that neurons that are more excitable than their neighbors tend to be recruited for encoding a new memory (Yiu et al., 2014). However, much remains to be elucidated concerning the machinery of memory allocation. One of the most interesting questions is whether the same ensemble of neurons is always dedicated to the same learning or whether an alternate ensemble is flexibly substitutable. This question is critical, because it might explain how repeated training strengthens the memory. It has been well recognized that established memories can be strengthened by repeated rehearsal learning (Ebbinghaus, 1913). This is assumed to be based on the principle that the same neurons and synapses are engaged in the same learning, thereby enhancing the particular plasticity. However, it has not been demonstrated experimentally that such a mechanism actually exists in the brain. To address this particular question, a pinpoint approach is required to manipulate a specific neuronal population that is sparsely distributed in the tissue while leaving their intermingled neighbors intact. However, classical lesion or pharmacological approaches are not technically feasible.

To circumvent this difficulty, we used the *c-fos*-promoter-driven tTA (tetracycline-controlled transactivator) transgenic (Tg) system in mice to manipulate specific subsets of neurons in which the promoter of the *c-fos* gene, an immediate early gene, was activated during a given time window (Matsuo et al., 2008; Reijmers et al., 2007). In the present study, we set out to examine the impact of silencing the neuronal ensembles activated during fear-conditioned learning on memory recall, and we then tested whether the silencing interfered with subsequent relearning in the Tg mice.

RESULTS

The Transgenic System for Reversible Suppression of a Behaviorally Activated Ensemble of Neurons

The neuronal activity-dependent *c-fos*-promoter-driven tTA Tg system permits tagging of specific subsets of neurons that are activated during a behavioral paradigm within a given time

Figure 1. Transgenic System of Activity-Dependent EGFP-TeNT Expression during a Given Time Window

(A) Schematic representation of the transgenic (Tg) system. The synthesis of EGFP-TeNT is regulated by neuronal activity via the *c-fos* promoter and is also dependent on the tetracycline-inducible expression system.

(B and D) Representative confocal fluorescent images showing the EGFP-TeNT expression (white arrow) in the hippocampal dentate gyrus of the TeNT^{c-fos} Tg mouse, shown by immunohistochemistry with an anti-GFP antibody (green), anti-NeuN or CaMKIIα antibodies (red), and DAPI (blue). Scale bars, 20 μm.

(C) Percentage of NeuN⁺ cells within somatic GFP⁺ cells (96.19 ± 1.91%; three mice, n = 44 cells).

(E) Percentage of CaMKIIα⁺ cells within somatic GFP⁺ cells (96.66 ± 1.68%; three mice, n = 49 cells).

window (Matsuo et al., 2008; Reijmers et al., 2007). In combination with this system, we utilized a tetanus toxin light chain (TeNT) to selectively suppress the synaptic transmission of tagged neurons and their relevant neural networks. TeNT selectively cleaves VAMP2 (also known as synaptobrevin), a synaptic vesicle protein essential for exocytosis, thereby blocking neurotransmitter release from presynaptic terminals (Link et al., 1992; Schiavo et al., 1992). By crossing the *c-fos*-tTA and tetO-EGFP TeNT (Yamamoto et al., 2003) Tg mice, we generated double-Tg mice (described as TeNT^{c-fos} Tg mice) that expressed the EGFP-TeNT protein under the regulation of the *c-fos* promoter in a doxycycline (Dox)-dependent manner (Figure 1A). In this system, when neuronal activity sufficient to activate the *c-fos* promoter occurs in the absence of Dox, the tTA transgene is expressed and drives the expression of the tetO-promoter-linked EGFP-TeNT selectively in those neurons activated by the behaviorally relevant events.

In situ hybridization analysis using a TeNT cRNA probe detected sparse signals selectively in the dentate gyrus of the hippocampus and the lateral and basolateral amygdala, along with very sparse signals in the hippocampal CA1, CA3 and neocortex

in fear-conditioned animals (Figure S1). Immunohistochemical analysis revealed sparsely distributed somatic GFP-positive cells, most of which were co-labeled with the neuron-specific marker NeuN and the excitatory neuron marker CaMKIIα (Figures 1B–1E). The GFP expression seen in some of the cell nuclei is derived from a Fos-GFP transgene that is expressed independently of the Dox-regulated system (Matsuo et al., 2008). In the CA1, CA3 areas and dentate gyrus of the hippocampus, larger numbers of cells expressing EGFP-TeNT were detected in fear-conditioned animals relative to home-cage controls and Dox-treated animals (Figure S2), confirming successful transgene suppression by Dox treatment and activity-dependent expression of TeNT in the absence of Dox.

Necessity of Learning-Activated Neuronal Ensembles for Memory Retrieval

We first examined whether the TeNT expression that was induced during learning affected the subsequent memory expression. The TeNT^{c-fos} Tg mice were removed from Dox for 3 days and were fear conditioned to elicit a long-term fear memory and to initiate the synthesis of TeNT selectively in the activated neurons. Mice were returned to their home cages and treated with Dox to suppress further induction of TeNT in neurons that were unrelated to the learning. On the following day, mice were re-exposed to the same chamber without footshocks to evaluate their contextual fear memory by measuring a freezing behavior (Figure 2A). The Tg mice showed significantly less freezing compared with wild-type (WT) littermates (Figure 2B; $p = 0.0018$, unpaired t test), suggesting an impairment of contextual fear memory retrieval in the Tg mice.

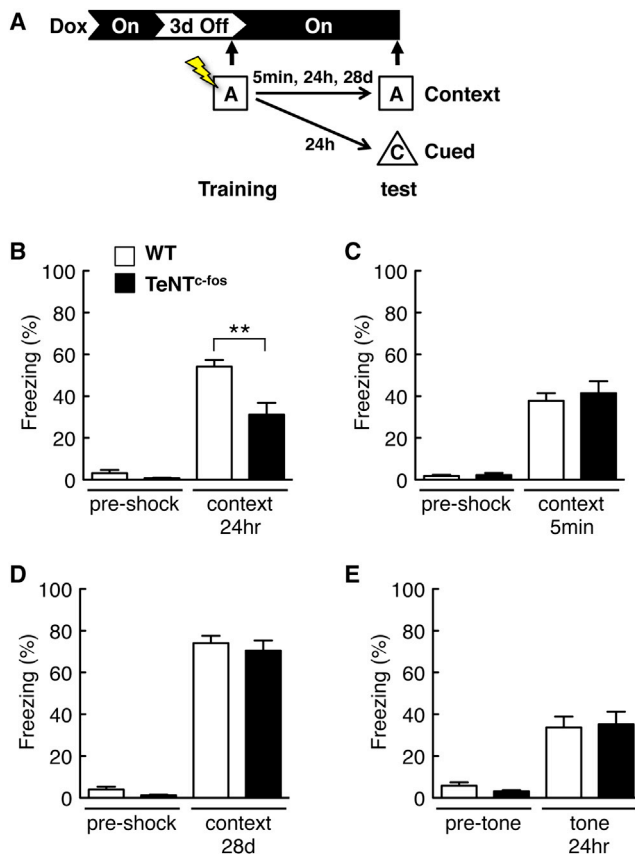

Figure 2. Requirement of Neuronal Ensembles Activated during Learning for the Memory Retrieval

(A) A schematic of the experimental design. Independent cohorts of animals were used for each experiment to avoid influences on subsequent tests. Animals were trained with fear conditioning after 3 days off Dox; they were subjected to contextual fear memory retrieval testing at different time points or to cued fear memory testing in a novel chamber (context C).

(B–D) The percentage of time spent freezing during the first 3 min of training session before footshock presentation (pre-shock) and during the retrieval test. Animals were tested 24 hr (B) (WT: $n = 12$, Tg: $n = 11$), 5 min (C) (WT: $n = 8$, Tg: $n = 9$), or 28 days (D) (WT: $n = 12$, Tg: $n = 14$) after conditioning. ** $p < 0.01$ (unpaired t test).

(E) The percentage of time spent freezing during the first 3 min in a novel chamber (pre-tone) and during the conditioned-stimulus tone presentation 24 hr after conditioning (WT: $n = 12$, Tg: $n = 11$).

Low levels of TeNT expression induced by home-cage activities during the off-Dox period could potentially impair the memory acquisition or neurological performance. To confirm that the Tg mice successfully acquired the contextual fear memory, we performed a retrieval test 5 min after conditioning (Figure 2C). The Tg mice froze significantly ($p < 0.0001$, paired t test), and the proportion of Tg mice that froze was comparable to that of WT animals ($p = 0.6087$, unpaired t test).

The impairment of contextual fear retrieval tested 24 hr after conditioning could reflect an inhibition in a process of either memory retrieval or consolidation. To discriminate these processes, we performed a memory retrieval test 28 days after training, when TeNT expression was reversibly suppressed (Fig-

ure S2). Both WT and Tg mice exhibited robust freezing, and there was no marked difference in the retrieval performance between them (Figure 2D; $p = 0.5698$, unpaired t test), suggesting that the deficit at the retrieval test 24 hr after conditioning was caused by an impairment in retrieval rather than in consolidation. It is notable that blocking the synaptic activity of specific neuronal ensembles after learning did not impair the long-term consolidation of contextual fear memory.

We next examined the impact of the TeNT-mediated silencing on conditioned-cue memory (Figure 2E). The Tg mice significantly froze during tone presentation in a novel environment (context C) 24 hr after conditioning, at levels comparable to WT controls ($p = 0.8546$, unpaired t test). The presence of normal cued fear expression in the Tg mice indicates that the observed TeNT-mediated impairment of contextual fear is not due to deficits in pain sensitivity, motivation, fear expression system, or other general neurological functions. Taken together, our results demonstrate that the TeNT-mediated suppression of neuronal ensembles that are naturally activated during fear conditioning results in a failure of the contextual fear memory retrieval. It further indicates that the reactivation of the ensemble engaged in memory acquisition is necessary for the retrieval.

Necessity of Neuronal Ensembles Activated during Initial Learning for Relearning

Next, we investigated whether inhibiting the reactivation of the neuronal ensembles that participated in the initial learning could hinder relearning. If the same subset of neurons is not necessarily assigned to the same learning and an alternative ensemble of neurons can functionally compensate for the inhibited ensemble, animals should acquire and express the fear memory. To test this idea, TeNT^{c-fos} mice were fear conditioned in context A in the absence of Dox to induce TeNT expression in the activated neurons. Then, they were retrained in the same chamber (context A) 24 hr after the initial training in the presence of Dox. Animals were subsequently re-exposed to the same environment to assess the contextual fear memory elicited by the second conditioning trial (Figure 3A). Notably, freezing was not increased compared with pre-retraining duration (Figure 3B; two-way ANOVA, $p = 0.5671$), indicating that the second training session failed to strengthen the contextual fear memory in these mice. In contrast, WT control animals exhibited substantially increased freezing after retraining (Figure 3B; two-way ANOVA, $p = 0.0045$; see Figure 3B legend), demonstrating that the memory was strengthened by the same additional training in context A. This also indicates that the failure of enhanced freezing in the Tg mice was not due to a ceiling effect.

To examine the specificity of the TeNT-mediated silencing to discrete neuronal representations, we investigated whether the Tg mice were able to acquire a new fear memory associated with a different context. Animals were fear conditioned in context A in the absence of Dox and retrained in a distinct chamber (context B) 24 hr later in the presence of Dox (Figure 3A). We found that they showed significantly more freezing during the retrieval test than during the period before shock presentation at the retraining session in context B (Figure 3C; $p = 0.0011$, paired t test). The enhanced freezing level was significantly higher in mice that were retrained in context B than in mice

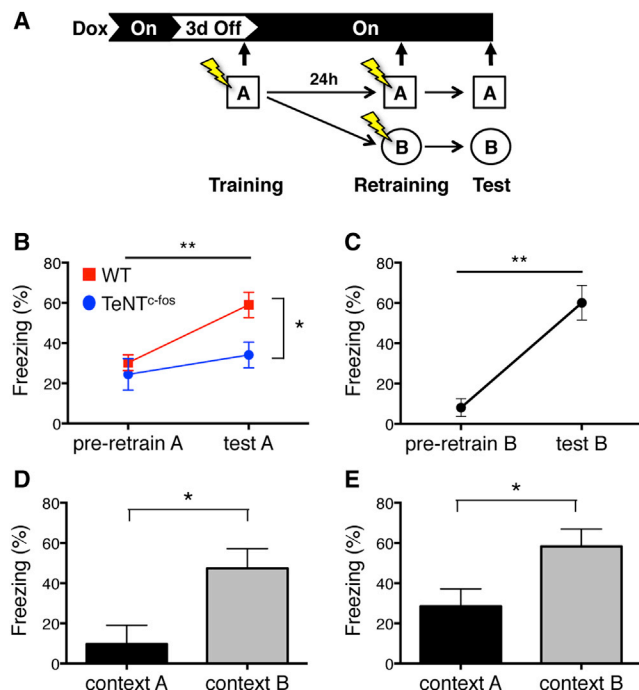

Figure 3. Requirement of Neuronal Ensembles Activated during Initial Learning for Additional Learning

(A) A schematic of the experimental design.

(B) The percentage of time spent frozen by wild-type (WT) mice ($n = 12$, red squares) and TeNT^{c-fos} Tg mice ($n = 12$, blue circles) during the first 3 min of retraining session before footshock presentation (pre-retraining) and during the test sessions in context A. Two-way ANOVA, retraining \times genotype interaction, $F(1,22) = 1.981$, $p = 0.1732$; retraining effect, $F(1,22) = 11.43$, $p = 0.0027$; genotype effect, $F(1,22) = 5.096$, $p = 0.0342$. WT mice were tested for whether the retraining in context A could strengthen the memory. For this experiment, animals were subjected to one-shock mild training so that the induced freezing level at the time prior to retraining ($30.23\% \pm 3.94\%$) was comparable ($p > 0.9999$, Bonferroni multiple comparison test) to that of Tg animals elicited by three-shock training ($24.44\% \pm 7.86\%$). They were then subjected to three-shock retraining in context A, which was the same treatment as applied to Tg animals, resulting in a significant increase in freezing behavior. ** $p < 0.01$, * $p < 0.05$.

(C) The percentage of time spent frozen by TeNT^{c-fos} Tg mice ($n = 8$) during the first 3 min of retraining session before footshock presentation (pre-retraining) and during the test sessions in context B. ** $p < 0.01$ (paired t test).

(D) The increase in freezing level of TeNT^{c-fos} Tg mice following retraining in context A (black bar) and context B (gray bar), showing a specific inhibition of learning in context A. * $p < 0.05$ (Mann-Whitney test).

(E) The same analysis in Figure 3D, excluding animals showing relatively higher freezing (over 20%) during the first 3 min of retraining. * $p < 0.05$ (Mann-Whitney test).

retrained in context A (Figure 3D; $p = 0.0148$, Mann-Whitney test). To avoid the possibility that the observed difference of enhanced freezing level was simply reflecting a ceiling effect, only mice showing a low freezing level (less than 20%) before the retraining were selected for analysis. The analysis revealed a significant difference in the increased freezing level between the contexts ($p = 0.0262$, Mann-Whitney test) (Figure 3E). Moreover, we compared the freezing level after training in either context A or context B using naive WT mice to eliminate the pos-

sibility that the training in context B might elicit a stronger freezing response than training in context A (Figure S3). Instead, conditioning in context B evoked a mild freezing, with no significant difference between the contexts ($p = 0.2105$, unpaired t test).

In summary, our data suggest that TeNT expression in neurons activated during memory encoding selectively inhibits relearning without disrupting the ability to acquire and retrieve a fear memory for distinct context. These results indicate that there is a mechanism ensuring that the same neuronal ensemble is engaged for the same learning to strengthen the memory and that it is not substitutable after the ensemble is allocated for the initial learning.

DISCUSSION

In the present study, we have generated a double-Tg mouse in which a synaptic transmission of neuronal ensembles activated by a given behavioral stimulus was selectively and reversibly inhibited. Using this Tg mouse, we have demonstrated the following: (1) suppression of neuronal ensembles that were naturally activated during fear-conditioned learning impaired the retrieval of the contextual fear memory, and (2) suppression of neuronal ensembles that were activated during fear-conditioned learning hindered relearning of the memory but did not interfere with new learning of a distinct contextual fear memory.

Identifying a neuronal circuit or population of neurons responsible for a particular behavior is one of the major challenges in neuroscience. Previous cellular imaging studies have found positive correlations between the activity of a small subset of neurons activated during learning and the performance of recall in several brain regions, such as the amygdala and hippocampus (Reijmers et al., 2007; Tayler et al., 2013). Thus, memory retrieval is assumed to involve the reactivation of neural ensembles that were established during encoding. To show the causal necessity, a series of experiments has elegantly shown that selective ablation or inactivation of a subpopulation of cells in the lateral amygdala that overexpressed CREB resulted in a disruption of the fear memory (Han et al., 2009; Zhou et al., 2009). However, these studies did not directly address whether the reactivation of the neuronal population that is naturally activated during learning is required for memory recall, because cells were artificially forced to allocate to the component constituting an associative memory. A genetic tagging system based on the neuronal activity-dependent *c-fos* gene promoter (Matsuo et al., 2008; Reijmers et al., 2007) enabled us to examine the impact of inhibition of a neuronal ensemble naturally induced by fear-conditioned learning on the retrieval of that memory and to demonstrate that the reactivation of that ensemble is required for recall of the contextual fear memory. This is consistent with the recently published results using Arc promoter and optogenetics (Denny et al., 2014).

The reason of intact cued fear memory is unclear. A previous report demonstrated rats with approximately one-third of their lateral amygdala neurons infected with the plasticity-block vector showed diminished cued fear learning, whereas animals with less than 10% of neurons infected showed no effects on learning (Rumpel et al., 2005). This suggests that the expression of

induced TeNT in the amygdala was possibly too small to block the memory engram of cued fear. Interestingly, CNS-specific *c-fos*-knockout mice also showed a deficiency in contextual, but not cued, fear memory (Fleischmann et al., 2003). Cells tagged by *c-fos*-promoter activation in the amygdala might therefore not necessarily be required for cued fear memory expression.

The *c-fos*-promoter-induced expression of the transgene in the hippocampal CA1 and CA3 regions of the TeNT^{c-fos} Tg mice was much smaller than that described in previous reports (Matsuo et al., 2008; Garner et al., 2012; Ramirez et al., 2013), possibly due to differences in the reporter gene expression system. In spite of the low expression of TeNT in these regions, retrieval and relearning of a contextual fear memory was impaired, implying that an extremely small population of cells might represent a particular memory. Alternatively, it is possible that inhibiting the memory engram in the dentate gyrus was sufficient to suppress contextual fear memory, supporting recent studies demonstrating causality between *c-fos*-activated cells in the dentate gyrus and memory engrams (Liu et al., 2012; Ramirez et al., 2013).

The hippocampus is an essential structure for contextual fear learning (Anagnostaras et al., 2001; Maren, 2001). Primarily, this is based on the fact that hippocampal lesions disrupt contextual fear learning. However, in some conditions, rodents with pre-training hippocampal lesions can acquire contextual fear memory, albeit less efficiently (Maren et al., 1997; Frankland et al., 1998; Wiltgen et al., 2006). Rats with post-training hippocampal lesions also exhibited severe retrograde amnesia but showed contextual freezing after retraining (Wiltgen et al., 2006). These results imply that an alternative system can compensate for the hippocampal damage at the structural level (Zelikowsky et al., 2013). However, lesion experiments destroy entire cells and circuits within the targeted region and thus may affect all processing that requires that structure. The current study examined whether compensation occurs for memory allocation during relearning at the cellular ensemble level, although the suppression was not specific for a particular structure. Interestingly, our results revealed that mice did not relearn when the neuronal ensemble engaged in the initial learning was compromised, indicating that functional compensation did not occur. Importantly, mice were capable of acquiring new memory for a different context, demonstrating an ensemble-specific, but not an overall non-selective, effect. Therefore, in contrast to cases in which the primary responsible region was entirely damaged (Maren et al., 1997; Frankland et al., 1998; Wiltgen et al., 2006; Zelikowsky et al., 2013), alternative ensembles are not likely to substitute for the primary cellular ensembles once they are allocated for a given representation. Suppression of relearning might require that the entire associative network containing the memory be compromised, because the formation of memory representation is likely to depend on complex interplay among memory traces in the brain, including the primary sensory cortices (Gdalyahu et al., 2012; Xie et al., 2014). Alternatively, it would be interesting to test whether suppression of ensembles in a particularly restricted brain region is sufficient to inhibit relearning.

Established memories can be strengthened by repeated rehearsal learning (Ebbinghaus, 1913). However, the underlying

neural mechanism remains to be elucidated. Our result provides remarkable insight, because it implies that the same neuronal ensemble is preferentially dedicated to the repetitive learning. This inflexibility of an ensemble could ensure the strengthening of synaptic connections across a specific subset of neurons by repetitive activation, thereby enabling memory enhancement.

EXPERIMENTAL PROCEDURES

Subjects

The TeNT^{c-fos} double-Tg mice were generated by crossing *c-fos*-tTA-Tg mice (Matsuo et al., 2008; Reijmers et al., 2007) with Tg mice expressing TeNT fused to EGFP under the control of the tetO promoter (Yamamoto et al., 2003). They were bred for more than nine generations on the C57BL/6J background and maintained as heterozygotes. Animals were housed socially (two to five animals per cage) and given food containing 50 mg/kg Dox and water ad libitum. Male Tg and WT littermate mice (11–14 weeks old) were used for behavioral experiments. All procedures were approved and conducted in accordance with the guidelines of Kyoto University and Osaka University on the care and use of laboratory animals.

Contextual and Cued Fear Conditioning

All behavioral experiments were conducted during the light period of the light/dark cycle. The mice were housed individually for at least 6 days before the onset of experiments, and they were handled for 4 days. They were placed in a novel rectangular chamber (33 × 25 × 28 cm, 100 lux) with white plastic side walls, a transparent plastic top and front and rear walls, and a stainless-steel grid floor (O'Hara) (context A) and were allowed to explore freely for 3 min. After the 3-min baseline period, three tone-shock pairings were presented. Each pairing consisted of a 30-s, 55-dB white noise ending simultaneously with a 2-s, 0.20-mA footshock. There was a 1-min interval between each pairing. The mice remained in the chamber for 30 s after the last footshock before being returned to their home cage. The total duration of training was 420 s.

For the contextual fear memory retrieval test, mice were returned to the conditioned chamber (context A) for 3 min to assess their contextual fear memory as measured by their freezing behavior at 5 min, 24 hr, or 28 days after conditioning. A different set of mice was used for each different time point to avoid the influences of prior retrieval and reconsolidation. To examine a cued fear memory, mice were placed in a novel triangular chamber made of opaque white Plexiglas (33 × 29 × 40 cm, 10–15 lux) that was located in a different soundproof room (context C) for 3 min (pre-tone), then subjected to 90 s of conditioned-stimulus tone exposure.

For the retraining experiment, a group of mice was retrained in context A 24 hr after the first training in context A. Another group of mice underwent the same training in context B, which consisted of a novel oval chamber with black and white checked patterned walls, a stainless-steel grid floor with staggered grid rods, and red light (15 lux) (see Figure S3). They were subsequently subjected to a contextual fear memory test in either context A or context B.

Freezing was scored and analyzed automatically by a charge-coupled device (CCD) camera-based system, TimeFZ4 (O'Hara). Images were recorded from the top of each chamber using the camera (two frames per second). For the analysis of images, the gap area (pixels) between the contour of the mouse in one frame and that in the next frame was identified. If the gap area was under 20 pixels for 2 continuous seconds, mice were judged to have exhibited freezing behavior. Freezing scores are expressed as the ratio of the freezing period to the experimental period.

Immunohistochemistry

Brains were fixed with 4% paraformaldehyde (PFA) in PBS at 4°C overnight and sectioned at a thickness of 50 μm using a vibratome (Leica). Free-floating slices were permeabilized with 0.3% Triton X-100 in 5% BSA/PBS at room temperature for 30 min, then rinsed with PBS. For enzyme antibody staining, permeabilized slices were incubated with primary antibody (rabbit anti-GFP antibody, Invitrogen) at room temperature overnight. Slices were rinsed with 0.3% Triton X-100/PBS three times for 10 min and then incubated with

secondary antibody (biotin-conjugated donkey anti-rabbit antibody, Millipore) at room temperature for 1 hr. Slices were then rinsed with 0.3% Triton X-100/PBS three times for 10 min and incubated with diluted avidin-biotinylated peroxidase complex (ABC-Elite, Vector Laboratories) at room temperature for 1 hr. Then, slices were rinsed with PBS three times for 10 min, and incubated with a solution containing 0.02% 3,3'-diaminobenzidine tetrahydrochloride (DAB; Sigma), 0.001% hydrogen peroxide, and 50 mM Tris-HCl (pH 7.6). Finally, slices were rinsed with PBS three times for 10 min and mounted in 50% glycerine. For the quantification of TeNT-EGFP-immunoreactive cells, images were acquired using an Axioplan 2 imaging microscope (Zeiss) equipped with an AxioCam HR CCD camera (Zeiss). Images were binarized using ImageJ (NIH), and TeNT-EGFP-positive cells were counted by an experimenter blind to the condition.

For fluorescent antibody staining, permeabilized slices were incubated with primary antibodies (rabbit anti-GFP antibody, Invitrogen; mouse anti-NeuN antibody, Millipore; mouse anti-CaMKII α antibody, Millipore) at 4°C overnight. Slices were then rinsed with PBS three times for 10 min and incubated with secondary antibodies at 4°C overnight (goat anti-rabbit Alexa 488, Invitrogen; goat anti-mouse Alexa Fluor 594, Invitrogen). After rinsing, slices were subsequently incubated with 4,6-diamidino-2-phenylindole (DAPI; Invitrogen) at room temperature for 10 min and then mounted in Slowfade Gold antifade reagent (Invitrogen). Fluorescent images were obtained using TCS SP8 confocal laser scanning microscopy with GaAsP hybrid detectors (Leica).

In Situ Hybridization

The 658-bp fragment of TeNT cDNA was amplified from genomic DNA isolated from tails of tetO-TeNT-Tg mice using the following PCR primers: 5'-TTTAACCCACCATCTTCATT-3' (forward), 5'-GTCCGCCAAAGTGAATAGT-3' (reverse). It was subcloned into pBluescript SK+ and used to make cRNA probes. Run-off antisense and sense transcripts incorporating digoxigenin-UTP (Roche Applied Science) were synthesized with T3 or T7 RNA polymerase, respectively. Tissue preparations and hybridization were performed as previously described (Matsuo et al., 1998), with some modifications. To detect the TeNT mRNA induced by fear-conditioned learning, the c-fos-tTA, tetO-EGFP TeNT, and bidirectional tTAH^{100Y}-tetO-taulacZ (Reijmers et al., 2007) triple-Tg mice were used, and they were removed from Dox for 4 days to enhance the TeNT mRNA expression. Three hours after fear conditioning, brains were removed and quickly frozen in powdered dry ice. Sections (14 μ m) were made using a cryostat. Sections were fixed in 4% formaldehyde for 30 min and treated with proteinase K (2 μ g/ml) in 50 mM Tris-HCl (pH 7.5), 5 mM EDTA at 37°C for 10 min. Sections were postfixed in 4% formaldehyde for 5 min to inactivate proteinase K and then acetylated for 10 min with 100 mM triethanolamine containing 0.25% acetic anhydride at room temperature. Sections were then dehydrated through graded ethanol. The riboprobe was diluted in hybridization solution (50% formamide, 10% dextran sulfate Na, 20 mM Tris-HCl [pH 8.0], 0.3 M NaCl, 0.2% sarcosine, 0.02% salmon sperm DNA, and 1 \times Denhardt's solution). Hybridization was conducted overnight at 50°C in a humid chamber. The hybridized sections were washed for 20 min in 5 \times saline-sodium citrate (SSC) at 60°C, then for 30 min in 50% formamide, 2 \times SSC at 60°C. After RNase A (10 μ g/ml) treatment for 30 min at 37°C, slides were washed again under high-stringency conditions. Immunodetection was performed using alkaline-phosphatase-conjugated anti-digoxigenin antibody (Roche Applied Science) for 90 min at 37°C, after preincubation with 1.5% blocking reagent (Roche Applied Science) for 30 min at room temperature. Sections were incubated in buffer (100 mM Tris-HCl [pH 9.5], 100 mM NaCl, 50 mM MgCl₂) for 10 min and then incubated in the dark in the same buffer containing the substrates Nitroblue tetrazolium (NBT; Roche Applied Science) and 5-bromo-4-chloro-3-indolyl phosphate (BCIP; Roche Applied Science). Color development was stopped by incubation in Tris-EDTA (pH 7.5) for a few minutes. The sections were coverslipped in 70% glycerol. Images were acquired using an Axioplan 2 imaging microscope (Zeiss) equipped with an AxioCam MRC CCD camera (Zeiss).

Statistical Analysis

All data were statistically analyzed using Microsoft Excel and Prism 6 (GraphPad Software) and are presented as the mean \pm SEM. Two-way ANOVA was followed with the Bonferroni multiple comparison test.

ACKNOWLEDGMENTS

I am grateful to M. Mayford and S. Nakanishi for providing c-fos-tTA and tetO-EGFP TeNT mice, respectively, and to M. Miwa for technical assistance. This work was supported by Grants-in-Aid for Scientific Research on Innovative Areas "Memory dynamism" and for Young Scientists (A); the Strategic Research Program for Brain Science from the Ministry of Education, Culture, Sports, Science & Technology of Japan; the Uehara Memorial Foundation; the Takeda Science Foundation; the Brain Science Foundation; and JST, PRESTO Program.
